Introduction to Parallel Computing with MPI and OpenMP

M.Cremonesi

2014

# Compiling notes

To compile programs that make use of MPI library:

```
Mpif90 | mpicc | mpiCC -o <executable> <file 1> <file 2> ... <file n>
```

Where: <file n> - program source files

<executable> - executable file

To start parallel execution on one node only:

```
mpirun -np <processor_number> <executable> <exe_params>
```

To start parallel execution on many nodes:

```
mpirun -np <processor_number> -machinefile <node_list_file> \  
<executable> <exe_params>
```

## E3 – exercise – Montecarlo Pi

The value of the constant  $\pi$  can be approximated also by recalling that, given  $A_c$  the area of the circle and  $A_s$  the area of the circumscribing square:

$$\pi = 4 \frac{A_c}{A_s}$$

Thus  $\pi$  could be approximated in a MonteCarlo style by counting the number of the random points in a square that are contained in the inscribed circle.

## E3 – exercise – Montecarlo Pi

Therefore the program may be written this way:

- Divide a square in an number of parts (as many as the processes)
- Generate a number of random points in the area of each process
- Calculate how many points fall in the inscribed circle
- Sum up number of points in the square
- Sum up number of points in the circle
- Divide the two numbers

Source code: Pi\_area

## E4 – exercise – Round pack

Starting from the code of the main program of the example `block_array`,  
define a data structure composed of:

2 x `MPI_LOGICAL`;

3 x `MPI_DOUBLE_PRECISION`;

9 x `MPI_CHARACTER`

Use `MPI_Pack` and `MPI_Unpack` to pack data in one buffer

Source code: `Round_Pack`

## E5 – exercise – Round struct

Modify the code of the previous Round\_Pack exercise to define a MPI derived data type that matches the data structure composed of:

2 x MPI\_LOGICAL;

3 x MPI\_DOUBLE\_PRECISION;

9 x MPI\_CHARACTER

Source code: Round\_Struct

## E6 – example – Mandelbrot set

In 1979 Benoît Mandelbrot, who was working at Thomas J. Watson Research Center of IBM, was studying what would have been later known as the *Mandelbrot set*. This mathematical object may be easily studied only by means of numerical computing, with the added support of computer graphics.

Defining the Mandelbrot set is quite easy:

Given the transformation  $z \rightarrow z^2$  in the complex plane, iterate it at each point of the circle of radius 2 centred in the origin.

The Mandelbrot set is the set of points that do not diverge outside this circle.

## E6 – example – Mandelbrot set

Of course points inside the circle with radius 1 always remain in the set, but there is no simple rules to decide whether the other points do belong to the set or not. The border of the set has fractal properties. Moreover, because of chaos behavior coming from exponent operations, points starting very closed together may diverge considerably.

The example program computes the Mandelbrot set in a given area (inside the radius two circle) and creates an image on the basis of how many iterations are needed to send a point outside the circle. The result is a well known image that can also be used to effectively check the correctness of the program.

# E6 – example – Mandelbrot set

The image is generated in PGM or PPM formats because they are very easy to remember and realize.

PGM format:

Row 1 – P2

Row 2 - <rows> <columns>

Row 3 - <Maximum value>

... <point values> ...

PPM format:

Row 1 – P3

Row 2 - <rows> <columns>

Row 3 - <Maximum value>

... <R G B point values> ...

## E6 – example – Mandelbrot set

The program could thus be sketched this way:

Define area in complex plane (squared for simplicity)

Define image size (squared for simplicity)

Define maximum iterations per point

Broadcast data to all processes

Parallel computation by domain decomposition

Gather results

Produce image

# E7 – exercise – Matrix multiply

Matrix row-column multiply is an example of program that can be easily parallelized and should have embarrassingly parallel behavior too.

Given the matrices  $A(L,M)$ ,  $B(M,N)$ ,  $C(L,N)$  try writing a parallel program that computes  $C = A \times B$

The program could be written this way:

Decide matrix sizes

Decide how to distribute computation

Parallel computation

Collect results

# E7 – exercise – Matrix multiply

Hint: given a range of rows and columns in the resulting matrix, their values depend only on a corresponding range of rows in A matrix and columns in B matrix

## E8 – example – Life game

John Conway's LIFE game has been described since 1970 on Scientific American. It consists in a very large checkerboard where there is a initial configuration of marked (or alive) cells. At each iteration per each cell the number  $F$  of the alive cells (taken among the 8 adjacent ones) is counted and the cell is marked alive or not according to the following rules:

The cell survives if  $2 \leq F \leq 3$

The cell dies if  $4 \leq F$  or  $F \leq 1$

The cell gets alive if  $F = 3$

The game rules are very simple but it is very difficult to predict the population evolution.

# E8 – example – Life game

As an example given a very simple initial configuration:

The evolution at next steps are:

## E8 - example – Life game

Programming difficulties for implementing a LIFE game are closed to issues encountered for programming PDE solvers with regular meshes.

A sequential program may be written in the following way:

- Decide board sizes (squared for simplicity) and number of iterations
- Allocate matrix  $A(:, :)$  for current state
- Allocate matrix  $B(:, :)$  for next state
- Choose an initial configuration
- Iterate:
  - store next state in matrix B by applying rules on matrix A
  - swap matrices

## E8 - example – Life game

Issues for parallel version:

- Decide board decomposition: divide board in disjointed portions
- At each portion of checkerboard add boundary 1 cell wide
- Distribute portions (with boundaries) to processes
- Iterate:
  - store next state in matrix B by applying rules on matrix A
  - send edges of portions to proper processes
  - receive boundary updates
  - swap matrices
